

Today's Lecture Plan

- Discussion of HW3 problems.
- Introduction to E20
 - Registers
 - Memory
 - Program Counter
- Comparison between E15 and E20.
- E20 Assembly language Instructions.
- E20 Machine Code Translation.
-

E20

- Architecture is more powerful than E15.
- E20 Assembly language is more expressive.
- Encoding of machine language is more complicated.

What's inside the E20 processor?

read-only register

\$0 (16-bit)

Comparison between E15 and E20 processors?

	E15	E20
registers	four 4-bit registers	seven 16-bit registers
memory	16 12-bit cells of read-only instruction memory	8192 16-bit cells of instruction/-data memory
instruction format	all instructions have 4-bit opcode field, two 2-bit register fields, and 4-bit immediate field	three formats: • 3-bit opcode field, three 3-bit register fields, 4-bit immediate field • 3-bit opcode field, two 3-bit register fields, 7-bit immediate field • 3-bit opcode field, 13-bit immediate field

E20 Assembly Instruction Format

E20 Assembly Instructions

- Instructions with three register arguments
 - add \$regDst, \$regSrcA, \$regSrcB
 - sub \$regDst, \$regSrcA, \$regSrcB
 - and \$regDst, \$regSrcA, \$regSrcB
 - or \$regDst, \$regSrcA, \$regSrcB
 - slt \$regDst, \$regSrcA, \$regSrcB
 - jr \$reg (remaining two operands will be filled with zero register) –
Jump Instructions
- Instructions with two register arguments
 - slti \$regDst, \$regSrc, imm
 - addi \$regDst, \$regSrc, imm
 - jeq \$regA, \$regB, imm – Jump Instructions
 - lw \$regDst, imm(\$regAddr) – Memory Reference Instruction
 - sw \$regSrc, imm(\$regAddr) – Memory Reference Instruction
- Instructions with no register arguments
 - j imm – Jump Instructions
 - jal imm – Jump Instructions

-

E20 Assembly Instructions (Pseudo Instructions)

- `movi $reg, imm`
 - The `movi $reg, imm` instruction is translated by the assembler as
`addi $reg, $0, imm.`
- `nop`
 - The `nop` instruction is translated by the assembler as
`add $0, $0, $0.`
- `Halt`
 - The `halt` instruction is translated by the assembler as an
`unconditional jump (j) to the current memory location.`
`endofprogram: j endofprogram`

E20 Assembler Directives

- `.fill imm`

Inserts a 16-bit immediate value directly into memory at the current location.

This directive instructs the assembler to put a number into the place where an instruction would normally be.

The immediate value may be specified numerically (positive or negative or zero) or with a label.

-

-

-

label

- A label is a symbol that represents a known memory address.
- A label name is a sequence of characters
 - The first character may be a letter or an underscore
 - Subsequent characters may be a letter, an underscore, or a digit
 - There must be at least one character.
 - Label names are not case-sensitive.
- A label may be declared in E20 assembly code by giving its name followed by a colon, preceding any instruction (including normal instructions, pseudo-instruction, and directives).
- The value of the label will be the address of the instruction that it precedes.
 - If the label precedes no instruction, the value of the label will be the address that a subsequent instruction would occupy
- A label's name may be used as the imm field of any instruction, assuming that the value of the label can be expressed in the number of bits allocated to that field.
- Labels make it easier to write E20 assembly language programs.
Why? – Please go to pollev.com/ratandeyto to write your answer.

Example of using label in E20 Assembly Code

```
first_label:
    movi $1, 1
    j first_label
    j second_label
second_label:
    movi $2, 2
```

Example of using label in E20 Assembly Code

```
first_label:
    movi $1, 1
    j first_label
    j second_label
second_label:
    movi $2, 2
```

```
ram[0] = 16'b001000000100000001;
ram[1] = 16'b0100000000000000;
ram[2] = 16'b0100000000000001;
ram[3] = 16'b001000001000000010;
```

Here's a sample of E20 assembly language.
Answer the questions based on your intuition.
How is this similar to E15 code?
How is this different from E15 code?

```
# Some simple math stuff

addi $1, $0, 5          # $1 := 5
addi $2, $1, -2         # $2 := $1 + (-2)
add  $3, $1, $2         # $3 := $1 + $2

addi $4, $0, 55         # $4 := 55
sub  $5, $4, $1         # $5 := $4 - $1
sub  $4, $5, $4         # $4 := $5 - $4

or   $6, $2, $5
and  $7, $2, $5

halt                      # end the program
```

What does this program do?
What is the final value of each
register?

Here's a sample of E20 assembly language.

How is this similar to E15 code?

How is this different from E15 code?

```
# A simple loop, counting down from 10

    movi $1,10           # Initialize counter to 10
beginning:
    jeq $1, $0,done      # if $1 == $0, go to done
    addi $1, $1,-1       # Decrement $1
    j beginning          # go to top of loop
done: halt               # we've finished
```

A *label* identifies a location in a program. Each label has a *name* and a *value*. The name is arbitrary. The value is the address of the memory where the label is defined.

Here, label **beginning** has value 1, and label **done** has value 4.

A label can be used as a destination of a jump, which is more convenient than giving the destination numerically.

do?
of each

What's in the E20?

The E20 has eight 16-bit general purpose registers, of which \$0 is read-only.
It has a 16-bit program counter.
It has 8192 16-bit memory cells.

The E20 memory is an 8192-element array.

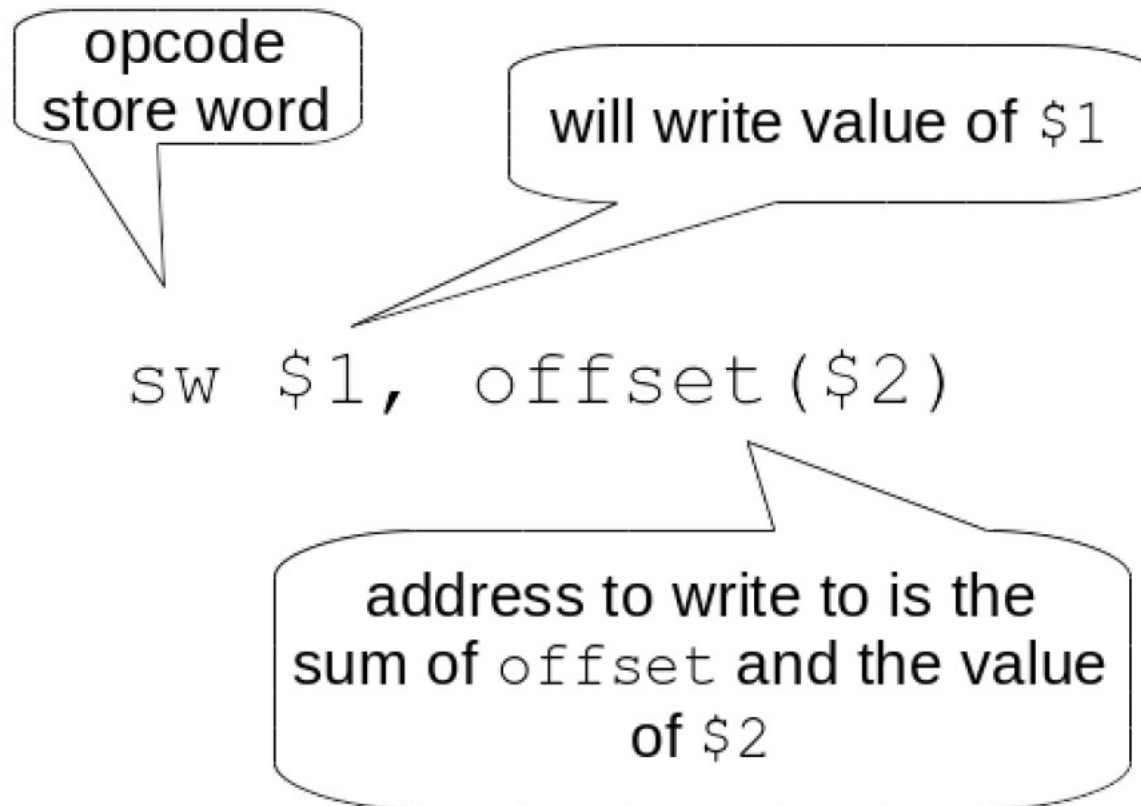

Each cell is 16-bits.

Each cell's value is initially zero.

A diagram showing a memory array structure. It consists of a yellow rectangular frame containing a blue rectangular area. Inside the blue area is a table with two columns: 'Offset' and 'Val'. The table lists values for offsets from 0 to 9, all of which are 0, and includes ellipses at both the top and bottom of the list. The entire diagram is set against a dark gray background.

Offset	Val
...	...
0	0
1	0
2	0
3	0
4	0
5	0
6	0
7	0
8	0
9	0
...	..

Store Value from Register to Memory Location

The E20 memory is an 8192-element array.

Each cell is 16-bits.

Each cell's value is initially zero.

Memory cells are changed with the **sw** instruction.

```
movi $1, 34  
sw $1, 4($0)
```

A diagram of the E20 memory array. It consists of a blue rectangular area with a yellow border. Inside, there is a table with two columns: 'Offset' and 'Val'. The table lists values for offsets from 0 to 9, with ellipses at the beginning and end. The value at offset 4 is 34, while all other values are 0. An arrow points from the assembly instruction 'sw \$1, 4(\$0)' to the row where offset is 4.

Offset	Val
...	...
0	0
1	0
2	0
3	0
4	34
5	0
6	0
7	0
8	0
9	0
...	..

```
movi $1, 34  
sw $1, 4($0)
```

The address to write to is specified as the *sum* of an immediate value and a register.

In this case, we first calculate the sum of 4 and \$0. That is the address to write to.

Offset	Val
...	...
0	0
1	0
2	0
3	0
4	34
5	0
6	0
7	0
8	0
9	0
...	..

Load Value from Memory Location to Register

opcode
load word

read value
will be stored in \$1

```
lw $1, offset($2)
```

address to read from is the
sum of `offset` and the value
of \$2

Memory cells are read with the `lw` instruction.
Given an address, they will copy the value of the memory cell into

`lw $2, 4($0)` ←

After this, \$2 will have value 34.

The address to read is specified as the *sum* of an immediate value and a register.

Offset	Val
...	...
0	0
1	0
2	0
3	0
4	34
5	0
6	0
7	0
8	0
9	0
...	..

Actually, I lied: the initial value of all memory cells is *not* zero.
In reality, the program is loaded into memory, starting at address zero.

Consider this program:

Assembly code	Machine code (bin)	Machine code (dec)
lw \$2, 4(\$0)	1000000100000100	33028
halt	0100000000000001	16385

Offset	Val
...	...
0	33028
1	16385
2	0
3	0
4	0
5	0
6	0
7	0
8	0
9	0
...	..

Here's a sample of E20 assembly language.

Notice in particular the use of **lw** and **sw** to access memory.

```
lw $1,var1($0)      # read from address var1 + 0
lw $2,var2($0)      # read from address var2 + 0
and $3, $1, $2      # AND the values together
or $4, $1, $2       # then OR them together
sw $3,var3($0)      # write the AND result into memory
movi $5, var3        # put the address (not the value!) in $5
addi $6, $5, var4

halt                # program ends
```

```
var1:
    .fill 30
```

```
var2:
    .fill 5
```

```
var3:
    .fill 0
```

```
var4:
```

A label can be used anywhere an immediate is accepted, including with opcodes **sw**, **lw**, and **movi**.

Here, we read from the memory location identified by label **var1** using **lw**.

What does this program do?
What is the final value of each
register?

7 general-purpose read/write registers

-2

7 general-purpose read/write registers

\$1 = 3

\$2 = 0

\$3 = 0

\$4 = 0

\$5 = 0

\$6 = 0

\$7 = 0

addi \$1, \$1, -5

?

Decimal (unsigned)	Decimal (signed)	Binary (2's complement)
3	3	0000000000000011
65531	-5	1111111111111011
65534	-2	1111111111111110

7 general-purpose read/write registers

\$1 = 3

\$2 = 0

\$3 = 0

\$4 = 0

\$5 = 0

\$6 = 0

\$7 = 0

addi \$1, \$1, -5

The E20 registers store 16-bit values.
Your simulator should always display
those values as unsigned decimal
integers.
So this is what we should see!

Decimal (unsigned)	Decimal (signed)	Hex (signed)
3	3	0000000000000011
65531	-5	1111111111111011
65534	-2	1111111111111110

7 general-purpose read/write registers

\$1 = 65534
\$2 = 0
\$3 = 0
\$4 = 0
\$5 = 0
\$6 = 0
\$7 = 0

addi \$1, \$1, -5

This is the "wraparound" effect.
Binary arithmetic means that
small numbers "wrap" to high
numbers and vice versa.

Decimal	Binary (8 bits)
3	0000000000000011
-5	1111111111111011
-2	1111111111111110

Wraparound happen in any language that uses fixed-width integers. C and C++ do this. Run this program and see for yourself.

```
#include <iostream>
#include <cstdint>
using namespace std;
int main() {

    // uint16_t is a 16-bit unsigned int type
    uint16_t x = 3;
    x = x - 5;
    cout << "3-5=" << x << endl; // prints 65534

    uint16_t y = 60000;
    y = y + 7000;
    cout << "60000+7000=" << y << endl; // prints 1464

    return 0;
}
```

E20 Machine Code Translation

- E20 Manual
 - Instruction set (Starting from Page # 11)
 -
- Need to be careful while translating **jeq** instruction.

Summary of Today's Lecture

- We discussed HW3 problems which is due today.
- We introduced E20 Processor.
 - Registers – 1 immutable and 7 mutable 16-bit registers
 - Memory – 8192 memory cells, each cell is 16-bit,
 - Program Counter – 16-bit register, stores the memory address of the currently-executing instruction ignoring Most Significant 3 bits.
- We compared between E15 and E20.
- We introduced E20 Assembly language Instructions.
- We introduced E20 Machine Code Translation.
- HW4 will be assigned today.

Reference

- Please read the E20Manual.
 - Available on NYU Brightspace.
 -
- Please read the lecture slide (05-e20 V2).
 - Available on NYU Brightspace

Plan for next lecture

- Branching and Iterative Statements
 - Comparison
 - Jump
- Array.
 - Using .fill and labels
- Subroutines/Functions
 - Using jal and jr instructions
- Recursive functions using stacks, jal, jr.
- Hardware Implementation: E20 Single Cycle.

E20 Recursion

What is a function?

- A function needs to be know where it was called from, and go back there when it's done
 - use `jal` and `jr`
 - return address stored in `$7`
- A function needs to accept parameters and return a result
 - we can decide to use registers
 - parameters in `$1`, `$2`, `$3`,
 - return value in `$1`

```
movi $1, 1
jal quadruple
add $2, $0, $1    # save result
```

```
movi $1, 5
jal quadruple
```

```
add $4, $2, $1    #  $\$4 = 4*1 + 4*5$ 
halt
```

```
quadruple:
```

```
add $1, $1, $1
add $1, $1, $1
jr $7
```

What is a function?

- But what happens when a function calls a function?
 - Saved return address and parameters will be lost

func1

func2

func3

What is a function?

- But what happens when a function calls a function?
 - Saved return address and parameters will be lost

What is a function?
